Abstract

Supratentorial hemangioblastomas have rarely been described in the literature. Pituitary stalk hemangioblastomas are extremely rare and almost always are associated with von Hippel Lindau disease. Herein, we report a sporadic case of pituitary stalk hemangioblastoma in a 36-year-old male and review the current literature regarding this pathology. In our case, complete resection of the lesion was achieved using the translabellar approach.

Categories: Endocrinology/Diabetes/Metabolism, Pathology, Neurosurgery

Keywords: hemangioblastoma, sporadic, translabellar approach, pituitary stalk, von hippel lindau

Introduction

Hemangioblastomas are histologically benign tumors of vascular origin that are usually cystic, occur in the cerebellum, and represent approximately 2% of all intracranial tumors [1-3]. Supratentorial hemangioblastomas are exceedingly rare, with only 116 cases reported in the literature from 1902 to 2004 [1,4-5]. In 30% of hemangioblastomas, there is an association with von Hippel Lindau (VHL) disease [2-3]. Von Hippel-Lindau complex, or von Hippel-Lindau syndrome, is a genetic disorder with an autosomal dominant inheritance pattern with variable penetrance characterized also by retinal angiomas, multiple renal, pancreatic, or hepatic cysts, pheochromocytoma, renal cancer, and the potential for malignant transformation in multiple organ systems. Sporadic pituitary stalk hemangioblastomas are extremely rare and almost always are associated with VHL disease.

Case Presentation

We present a 36-year-old male who was admitted to our department due to the gradual worsening of the left eye vision. Ophthalmologic evaluation of the patient's retina showed no remarkable findings while ocular examination showed visual acuity 8/10 on the right eye and 1/10 on the left eye. The formal visual field testing, by using the standard Goldman perimetry study, revealed a left upper temporal quadrant deficit. Further neurological examination was normal. No endocrine dysfunction was identified preoperatively. Brain computed tomography (CT) scan revealed a sellar mass with sellar enlargement and dorsum sella erosion (Figure 1). Further investigation with brain magnetic resonance imaging (MRI) demonstrated a 3 cm sellar mass, intensely and homogeneously enhancing after the intravenous (IV) administration of gadolinium, with suprasellar extension, inferior displacement of the infundibulum, and upward displacement of the optic chiasm and anterior communicating artery complex (Figures 2-4).

The patient underwent a surgical operation via a transglabellar approach (Figures 5-6). A highly vascularized tumor was recognized and total resection was achieved (Figures 7-8). The excised surgical specimen was sent for histology (Figures 9-15).

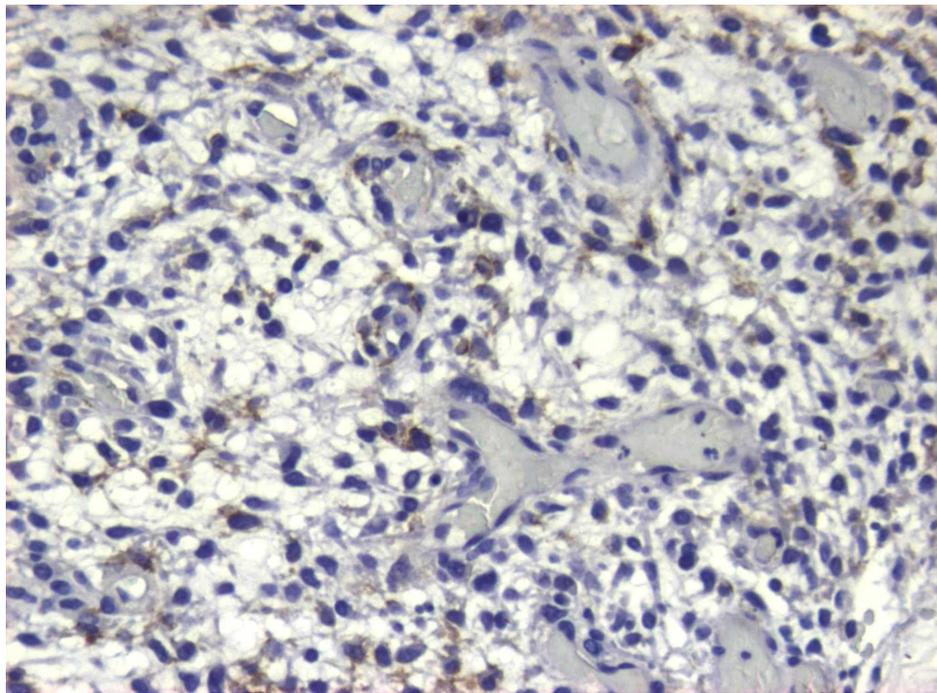

FIGURE 15: Immunoreactivity for EMA

EMA: epithelial membrane antigen

Histopathological examination of the tumor showed a cellular proliferation of stromal cells, interlaced by numerous thin-walled vessels, foam, and vacuolated histiocytes. No mitoses were identified. In histochemical and immunohistochemical stains, stromal cells were positive to vimentin and epidermal growth factor receptor (EGFR) and in limited locations, also positive in EMA and neuron-specific enolase (NSE) while negative in CK7, CK20, CK 5/6, glial fibrillary acidic protein (GFAP), pancytokeratin, CK34βE12, S-100, and α -inhibin. The cellular proliferation index ki67 was less than 1%. Differential diagnosis included angiomatous meningioma, angioblastic meningioma, transitional angioblastic, and angioblastomatous meningioma. The overall histological diagnosis was capillary hemangioblastoma (World Health Organization (WHO) Grade I).

Postoperatively, the patient had considerable improvement in his visual acuity and temporal quadrant deficit. Except for transient diabetes insipidus, the rest of the postoperative course was uneventful, including any endocrine dysfunction.

After the histological diagnosis, initially, VHL syndrome was excluded via further imaging studies, including ophthalmic ultrasonography, abdominal, cervical, thoracic, and lumbar MRI. Although imaging studies were negative for other tumors and there was no known family history, genetic screening was suggested to the patient for von Hippel-Lindau gene mutations. No residual tumor was recognized in the brain MRI six months after surgery and the genetic test was negative for VHL mutations (Figure 16).

Discussion

Hemangioblastomas are benign lesions that originate from the vascular system and have been reported in a variety of locations in the central nervous system. These tumors present as either isolated or multiple lesions. Isolated lesions occur in 80% of patients with VHL syndrome, and in 95% of patients without this disease. They are usually found in the cerebellum, but they have also been reported in the spinal cord, the brain stem, and, in rare cases, in the cerebrum. Typically, patients in the fourth and fifth decades are affected, but there are also reports of congenital lesions. There are only 132 previous reports in the literature of supratentorial hemangioblastomas [6]. Reports of intrasellar [7], suprasellar [8], and intraventricular locations [9] have been documented. Although histologically benign, occasionally, the tumor may spread along the subarachnoid space and especially after a surgical procedure, but no metastases have been testified. Histopathologically, they are characterized by two major components: vacuolated stromal cells and a capillary network. They do not have a true capsule, but the tumor margin is well-circumscribed and may be either cystic or solid.

Von Hippel-Lindau disease is positively correlated with supratentorial hemangioblastomas when compared with non-supratentorial central nervous system hemangioblastomas, particularly when present in the sellar/suprasellar region [6]. Pituitary stalk hemangioblastomas are strongly associated with VHL disease and their occurrence outside the VHL syndrome is a rare phenomenon. To our best of knowledge, after searching Pubmed/MEDLINE, only nine sporadic cases of pituitary stalk hemangioblastomas, including our case were found (summarized in Table 1) [10-20]. In general, pituitary stalk hemangioblastomas are indistinguishable from craniopharyngiomas based on MRI findings, making the preoperative diagnosis of hemangioblastoma extremely challenging. Both tumors can be isointense on T1-weighted sequences, hyperintense on T2-weighted sequences, or homogeneously enhancing after gadolinium administration. In some cases, flow voids can be identified, orientating the diagnosis towards hemangioblastoma. Angiography can be used as a tool for the differential diagnosis, revealing a highly vascularized tumor in the case of hemangioblastoma.

TABLE 1: Literature review of sporadic pituitary stalk and suprasellar hemangioblastomas

CT: computed tomography; PRL: prolactin; GTR: gross total resection; ACTH: adrenocorticotropic hormone; GH: growth hormone; MRI: magnetic resonance imaging; MRA: magnetic resonance angiogram; FSH: follicle-stimulating hormone; LH: luteinizing hormone

Surgical resection (open or endoscopic) of these lesions is necessary when they become symptomatic, usually presenting with visual defects and endocrine dysfunction. Due to their high vascularity, open craniotomy is generally preferred in order to prevent uncontrolled bleeding and partial excision, but this approach results more often in pituitary stalk excision as compared to the transsphenoidal approach [7,9,16]. Total removal should be the main surgical goal, as these benign neoplasms tend to easily recur after partial excision. The role of radiotherapy is yet to be determined as an adjuvant treatment modality in cases of sporadic sellar/suprasellar hemangioblastomas [7,13].

Conclusions

Our study reports the ninth case of sporadic pituitary stalk hemangioblastoma, in which total resection was achieved by the transglabellar approach that is not so commonly used. Preoperative imaging should be

thorough regarding highly vascularized lesions and angiography should be generally included in the preoperative setting, as it can be helpful not only as a diagnostic tool but also as a treatment modality with the embolization of large feeding vessels in cases of hemangioblastomas. Large multicenter studies are necessary to evaluate the role of radiotherapy as a primary or adjuvant treatment.
